Abstract

Background and aims. The aim of this study was to compare the biocompatibility of calcium-enriched mixture cement (CEM), composite resin and nano-particled mineral trioxide aggregate (NP-MTA) using human gingival fibroblasts.

Materials and methods. A comparative in vitro cell culture study was carried out using 60 single-rooted teeth which were assigned to the following four groups: 1) untreated healthy group (control); 2) restored with composite resin; 3) CEM cement; 4) NP-MTA. The MTT assay was used to measure the viability of fibroblasts attached to each specimen and scanning electron microscopy (SEM) was used for describing cell morphology.

Results. After 24 hours of incubation, the survival rates for composite resin and NP-MTA were 74.1% and 76.9%, respectively, which were significantly lower than the value in the control group, while both were equally biocompatible. No statistically significant difference was found between the control group and CEM cement samples (94.3%). After 3 days of incubation, some increases in the viability of fibroblasts were detected in the composite resin and NP-MTA groups, with their survival rates being 89% and 93%, respectively. Conversely, in the CEM cement group, the survival rate decreased to 80.7%, which was significantly lower than that in the control group (P = 0.0001).

Conclusion. The results of in vitro tests indicated that on days 1, 3 and 5 after incubation, composite resin, CEM cement and NP-MTA exhibited acceptable biocompatibility, provided they were allowed to set for 24 hours before exposure to the cells.

Key words: Gingival fibroblast attachment, Mineral trioxide aggregate, Calcium-enriched cement.
Introduction

Damage to the periodontal attachment may result from periodontal disease and/or iatrogenic factors such as tooth bleaching; orthodontic movements, endodontic flare-ups and acute trauma. These damages may lead to defects like cervical resorption and root perforation. They may appear just below the junctional epithelium or on the root surface, which then may result in associated bony defects. There is an ongoing debate on the most suitable material for repair of root defects depending on the extent and depth of resorption. The material used is critical as it should be biocompatible, with good sealing ability. Various materials such as MTA, compomer, amalgam, composite resin, resin-modified glass-ionomer, reinforced zinc oxide-eugenol cement and glass-ionomer cement are frequently used to treat these defects.

While MTA has proven to have ideal biocompatibility with many other favorable properties, the difficulties in its handling and long setting time have led to numerous attempts in finding a proper alternative material. CEM is a novel endodontic cement with promising properties. Many studies have compared CEM and MTA and found that CEM has favorable properties, such as good biocompatibility, flow and sealing abilities similar to MTA. Also, CEM has good handling properties and shorter setting time compared to MTA, and does not lead to discoloration of the teeth. Although CEM has been compared to MTA in many different aspects, most such studies have analyzed this material only in comparison to those of similar compositions (different brands of MTA and Portland cement). Studies comparing the qualities of CEM with those of other materials such as composite resins are lacking. Composite resins as esthetic dental materials are in demand. But, due to the release of unbound monomers and co-monomers, biocompatibility has remained a major concern. However, some studies have shown that composite resin cytotoxicity is only high for a short period and diminishes over time. In addition, many different additives have been used to overcome undesirable properties of MTA. One attempt was the use of different nano-particle elements in the composition of MTA. Nevertheless, NP-MTA is a relatively new material with insufficient evidence and research to support its use in the clinical setting.

Reformation of a normal attachment apparatus, including junctional epithelium and connective tissue attachment, is mainly carried out by fibroblast cells of gingival connective tissue. Most of the available studies used PDL fibroblasts for testing cell attachment properties of dental materials. However, the behavior and reactions of gingival and PDL fibroblasts are not similar from various aspects. The aim of this study was to compare the biocompatibility properties of CEM, composite resin and NP-MTA using human gingival fibroblasts.

Materials and Methods

This study was designed as a comparative cell culture study in vitro. Extracted teeth were collected after obtaining written informed consent from patients, and then 60 single-rooted teeth based on the inclusion criteria (healthy single-rooted teeth with no history of periodontal disease or any sort of defects) were selected for this study. They were assigned to the following four groups: 1) untreated healthy group (control); 2) restored with composite resin; 3) restored with CEM cement; 4) restored with NP-MTA.

Preparation of Root Specimens

After removing the crown and the apices of the teeth, the middle third of each root was sectioned longitudinally in the buccolingual plane, and rectangular root plates were obtained, measuring approximately 5×5×7 mm. The defects were then artificially created on 45 root slices (except in controls). Before filling, all the slices were sterilized in 70% ethanol containing 4% antibiotic (penicillin-streptomycin) for 30 minutes. Then they were rinsed three times with phosphate-buffered saline (PBS) solution. Afterwards, the defects were restored with composite resin, NP-MTA and CEM under aseptic conditions. The materials were allowed to set for 24 hours before exposure to the cells.

Preparation of Test Materials

The materials tested were CEM (Bionique Dent, Tehran, Iran), composite resin (Z350, 3M ESPE, USA), and NP-MTA (experimental product that has not yet been released into the market). For each material, 15 dental blocks with cavities were prepared, except for the control group which had smooth surfaces with no cavities prepared. CEM and NP-MTA were prepared according to the manufacturers’ instructions under aseptic conditions and placed in the cavities created in the dental blocks. The surfaces were smoothed-out using a sterile plastic instrument. For the composite resin group the blocks were first acid-etched (Dentsply, York, PA, USA) and rinsed with water. After removing the excess water, dentin bonding agent (Scotchbond, 3M, MN, USA) was applied and light-cured; then, composite resin was placed in the cav-
ties and light-cured according to the manufacturer’s instructions. The materials were allowed to set for 24 hours.

**Preparation of Samples**

Before cell seeding on filled dental slices, all of them were placed in a 24-well culture plate (SPL, Korea) and UV-irradiated for 20 minutes on each side. Human gingival fibroblast cells (HGF) (NCBI: CIS2) were purchased from the cell bank (Pasteur Institute, Tehran, Iran). The cells were kept in Dulbecco’s Modified Eagle’s Medium (DMEM) (Gibco, USA) supplemented with 10% fetal bovine serum (FBS, Gibco, USA) and 1% penicillin-streptomycin (Gibco, USA) and incubated at 37°C, 95% humidity and 5% CO₂. In the logarithmic phase of growth, the cells were extracted by Trypsin-EDTA enzyme (Gibco, USA) and transferred to each well of a 24-well plate on a dental slice (50,000 cells in 1 mL of DMEM per well).

**Quantitative Cell Viability and Proliferation Assay**

Methyl-tetrazolium bromide (MTT) assay was performed to evaluate the survival and proliferation of gingival fibroblasts on days 1, 3 and 5 after the cell culture. After incubation (1, 3 and 5 days), root slices at each time were placed in a new 24-well culture plate. The fresh culture medium with 10% MTT dye was added to each well. The plates were incubated at 37°C for 3 hours. Afterwards, the medium of each well was extracted and replaced by dimethyl sulfoxide (DMSO) solvent, solubilizing the formazan crystals. Next, 100 μL of each purple solution (from each well of the 24-well plate) was transferred into each well of a 96-well Elisa reader plate in triplicate. The absorbance of solution dye was measured by an Elisa reader (Anthous 2020, Austria) at 570 nm. The cell viability percentage of each experimental group was expressed as a ratio relative to that of the control group (100% viability).

**Scanning Electron Microscopy**

SEM analysis was performed on fibroblasts attached to the root surfaces. The samples were rinsed with PBS and fixed on the root surfaces using 2.5% glutaraldehyde (Merck, Germany) for 2 hours. Then, the slices were placed in 1% osmium solution (TAB, England) for 1 hour. Gradient concentrations (30%, 50%, 70%, 90%, and 100%) of ethanol were used to dehydrate the specimens. The specimens were dried and then sputter-coated with gold.

**Statistical Analysis**

The MTT assay was used to measure the viability of the fibroblasts attached to each specimen. Data were expressed as mean ± SD. The results were analyzed using one-way ANOVA, followed by post hoc Tukey-Kramer test. P-values < 0.05 (indicated with a star on graphs) were considered significant.

**Results**

The results after 24 hours of incubation indicated cellular attachment and primary toxicity of the materials, while the results of 3-day and 5-day incubation periods were indicative of cellular proliferation and viability as well as the materials’ cytotoxicity. The materials with normalized viability rates below 70% were considered cytotoxic. Nevertheless, the results of our study indicated that after 24 hours of setting time, all the tested materials were biocompatible (Table 1).

Reduction in the number of fibroblasts attached to CEM cement continued for up to 5 days of incubation. There was also a reduction in the survival rate of the cells attached to NP-MTA and composite resin. NP-MTA and composite resin resulted in lower viability compared to the control group; the survival rates in the afore-mentioned 2 groups were 89.9% and 77.3%, respectively. Nevertheless, the survival rate in the NP-MTA group was significantly higher than that in the CEM cement (P = 0.0005) and composite resin (P = 0.0002, Figure 1) groups.

Discussion

Root defects, namely perforations and resorption, are now being treated using various kinds of materials such as MTA, compomer, amalgam, composite resin, resin-modified glass-ionomer cement, Plus glass-ionomer cement.7,9,10 Numerous studies have compared the effect of these materials on gingival fibroblast cell adhesion (Table 2). Huang et al43 evaluated the effect of resin-modified glass-ionomer cement, compomer, and composite resin on human gingival fibroblasts by performing an in vitro MTT assay. The results in treated groups indicated the best cell viability and attachment in the compomer group. In the in vitro study carried out by Haglund et al,9 cell growth, cell morphology, and cytokine (interleukin [IL] 1β and IL-6) production in murine fibroblasts in contact with MTA, amalgam, IRM, and Retroplast were evaluated. The total cell numbers cultured with fresh IRM were significantly less than that cultured with other fresh materials and there was no statistically significant difference in cell count between the fresh MTA group and the fresh amalgam group. In addition, IL-1β or IL-6 production was not detected in any of the root-end filling material groups. Camp et al7 assessed the attachment of human gingival fibroblasts and PDL fibroblasts to different root-end filling materials (Geristore, ProRoot, Tytin amalgam and SuperEBA) and also evaluated whether integrins were responsible for any attachment. They reported greater cell attachment to Geristore and concluded that integrins did not mediate direct attachment of gingival fibroblasts to the root-end filling materials. Similar results were obtained in a study carried out by Al-Sabek et al44 and Al-Hiyasat et al. In another research, Raldi et al1 evaluated the fibroblast attachment and the morphological changes of simulated cervical root resorption after irradiation with high-power lasers and the use of MTA. They concluded that irradiation with Er:YAG and diode lasers caused morphological changes in the dentinal surfaces of simulated resorption areas that favored cell adhesion and that MTA showed lower biocompatibility than the irradiated groups but allowed cell adhesion. Mozayeni et al26 assessed the cytotoxic effects of IRM, MTA and CEM on L929 mouse fibroblasts using the MTT assay. The assay was based on the reduction of the soluble yellow MIT tetrazolium salt (Sigma, Germany) to a purple insoluble formazan crystals produced by mitochondrial succinic dehydrogenase enzyme. The sensitivity of this method is above 95%. They showed that the lowest cytotoxic values recorded were expressed by MTA subgroups followed by CEM cement; while IRM subgroups were the most cytotoxic root-end/dental material. Ghasemi et al45 evaluated the effect of CEM and ProRoot MTA (WMTA) + disodium hydrogen phosphate (DSHP) on the induction of bone morphogenic protein-2 (BMP-2) by human gingival fibroblasts (HGF) in comparison to WMTA. The results indicated greater amounts of BMP-2 using WMTA followed by WMTA+DSHP and CEM.

The favorable biocompatibility of CEM among other properties has been widely investigated and CEM can be considered as an alternative to MTA. NP-MTA is a relatively new material and only a few studies have tested its physical and biological properties. Composite resins have also been investigated by many studies, but their biocompatibility is often

Figure 1. Percentages of cell viability of attached HGF cells on treated teeth (24 hours after setting/treating) in comparison with controls (untreated tooth). A: comparison of materials, B: comparison of time effect.
compared to glass-ionomers or other similar materials. Therefore, there are few studies on the comparison of these two different types of resins and mineral oxides (MTA or CEM cement). The results of our in vitro study showed that on day 1, day 3 and day 5 after incubation, all of the tested materials (composite resin, CEM cement and NP-MTA) would exhibit favorable biocompatibility, if allowed to set for 24 hours before exposure to the cells (Figure 2). Furthermore, CEM cement showed...
the best primary viability, while after 5 days of incubation the highest survival rate belonged to the NP-MTA group. This can be interpreted as a time-dependent increase in toxicity of CEM cement and a time-dependent decrease in toxicity of NP-MTA. The CEM cement group results of our study are consistent with those of others,26,40-42 all of which have demonstrated the biocompatibility of CEM cement. Still, none of them compared CEM (or other similar materials such as MTA) to a completely different material like composites resin. Although there are many concerns about the cytotoxicity of composite material like composites resin. Although there are contradictory results were reported by Huang et al51 and Gallorini et al.50 This can be due to the difference in the usage of different types of composite resins and different methods of application; the main reason is probably the lack of suitable polymerization. In the current study, the composite resin was first light-cured and then allowed to continue polymerization for 24 hours before exposure to cells; therefore, higher viability of cells was achieved. Thus, according to the results of the present study, composite resins are biocompatible after proper polymerization (Figure 4).

Conclusion

Under the limitations of this in vitro study, all the tested materials showed favorable biocompatibility after 24 hours of setting, but further studies are needed to confirm the physical and biological properties of NP-MTA. CEM cement showed the best primary viability, while after 5 days of incubation the highest survival rate belonged to the NP-MTA group.
